

Data Management

1 RELATIONAL MODEL

Aspetti positivi :

1. molto rigido come regole.
2. il RDBMS sfrutta le proprietà ACID :
 - A : Atomicity : serve affinché l'operazione o avviene su tutti i dati o non avviene, ad esempio se vi è un aggiornamento nei dati questo aiuta affinché i dati non vengano aggiornati solo parzialmente.
 - C : Consistency : I dati o il nuovo dato che viene aggiunto rispetta lo schema prestabilito. E se si viola la consistenza con un'operazione tutta l'operazione fallisce.
 - I : Isolation : gestisce come l'integrità delle transazioni sono viste dall'utente. E garantisce che durante un'operazione (query) non vengano svolte altre operazioni. E che lo stato del database venga modificato solo prima della fine della query.
 - D : Durability : garantisce che una transazione effettuata sopravvivrà per sempre. Anche se il sistema crasha dovuto grazie ai server di backup e log files.

Il RDBMS esiste già da 35 anni quindi è ben sviluppata e molto conosciuta, molti dati sono ancora salvati in questo formato ed è efficace ancora per molte operazioni. Gli aspetti limitanti sono:

1. un attributo può avere solo un valore.
2. non è compatibile con molti linguaggi moderni.
3. molto rigido come linguaggio
4. non accetta i loop.
5. Per i RDBMS :
 - Difficile modificare le tabelle.
 - La performance,

Nei RDBMS la performance (inteso come velocità) dipende da vari fattori:

- Numero delle righe
- Tipo di operazione
- Algoritmo scelto
- La struttura dati scelta

Per Scaling Up intendiamo potenziare le macchine, mentre per Scaling out intendiamo aggiungere macchine, per i RDBMS è più facile Scale up che Scale out. Ulteriormente il costo è un altro dei problemi, installare il software richiede un costo molto alto e hardware molto complesso. Inoltre se continuiamo a aggiungere server (scaling out) il prezzo dell'Hardware aumenta esponenzialmente mentre il tempo di risposta scende asintoticamente.

Di fronte a questi svantaggi sorge una nuova "tecnologia" i NoSQL(Not Only SQL), le proprietà di NoSQL sono:

1. Non ha nessun schema o modello prefissato
 - A differenza dei modelli SQL nei quali bisogna prima definire il modello, qui nei NoSQL non esiste un modello rigido.
 - Per aggiungere un nuovo attributo non vi è bisogno di cambiare il modello a differenza dei SQL
 - I modelli NoSQL seguono l'assunzione del mondo aperto (ciò che non è vero è sconosciuto(ma non per forza falso)) mentre SQL segue l'assunzione del mondo chiuso (solo ciò che è noto come vero è vero)
2. Segue il teorema CAP:
 - E' impossibile per un sistema informatico distribuito(vuol dire sistemi interconnessi tra loro e la comunicazione avviene solo attraverso messaggi) fornire simultaneamente le tre garanzie(Infatti può soddisfare solo 2 di esse)
 - (a) **(C)**Coerenza : Tutti i nodi vedano gli stessi dati allo stesso istante. Se è assente allora una soluzione è mostrare il dato precedente alla modifica cioè non quello più recente.
 - (b) **(A)**vailability(Disponibilità) : La garanzia che ogni richiesta ottenga una risposta su ciò che è fallito e ciò che ha avuto successo. Se è assente aspetterò per lunghi tempi senza ricevere una risposta.
 - (c) **(P)**artition Tolerance(Tolleranza sulle partizioni) : Il sistema funziona anche dopo aver perso un numero arbitrario di pezzi del sistema.
 - I sistemi RDBMS sono dei software CA, ed è possibile creare dei modelli RDBMS basati sul CAP
 - I sistemi NoSQL sono dei sistemi solitamente CP o AP.
 - Uno preferisce la disponibilità sulla coerenza, perché è meglio vedere un vecchio dato non coerente che vedere un errore di fallimento di caricamento dei dati.
3. Segue Principio BASE:
 - Basic Availability : completare una richiesta anche se parzialmente consistente, ad esempio nel caso di fallimento. E' possibile fare ciò grazie al fatto che usa server sparsi ovunque con un grado di replicazione del database e in caso di malfunzionamento del database richiesto non tutto il sistema cede la Disponibilità.
 - Soft State : Abbandonano la richiesta di consistenza dei ACID praticamente completamente.
 - Eventual consistency : I sistemi NoSQL richiedono che a un certo punto i dati convergeranno a uno stato consistente (non si fa garanzie sul quando), e quindi

prima di allora ho una consistenza ritardata cioè prima del momenti dello stato consistente posso ricevere come risposta qualunque valore come risposta di una query.

ACID

- Forte Coerenza
- Poca disponibilità
- Pessimo “Multitasking”
- Complesso

BASE

- Coerenza debole
- Disponibilità è la cosa principale e sacrifica per questo (CAP)
- Veloce e Semplice

Esempi e tipologie di modelli NoSQL :

1. Key Value (Dynamo, Voldemort, Rhino DHT) : Sono delle tabelle con chiavi che si riferiscono/puntano a un certo dato, è molto simile a Document based.
2. Column family (Big Table, Cassandra) : In grado di salvare grandi quantità di dati, la chiave colonna si riferisce a un certo dato raggruppato in collona.
3. Document based (CouchDB, MongoDB) : Di solito salvati con file JSON, salvati come una <chiave – valore>. E’ facile ricercare dati in questo formato. JSOM è basato su due strutture :1) chiave – valore per gli oggetti e 2) lista ordinata di elementi.
4. Graph based (Neo4J, FlockDB) : Uso i vertici/nodi e archi per rappresentare i dati e legami tra di loro. E’ difficile fare scaling con i grafi.

Abbiamo che dobbiamo sacrificare o la dimensione del database o la sua non complessità:

2 MongoDB

MongoDB is as already mentioned a document based management system, with the data stored in Bson (Binary Json), and the access to data is possible thanks to indexes. Compared to the SQL DBs Mongo doesn't have the join feature. The name changes are:

RDBMS		MongoDB
Database	⇒	Database
Table, View	⇒	Collection
Row	⇒	Document (BSON)
Column	⇒	Field
Index	⇒	Index
Join	⇒	Embedded Document
Foreign Key	⇒	Reference
Partition	⇒	Shard

In case of a massive data upload one might decide to:

- Disable the acknowledgment(ack) of the data, which is a signal passed between communicating processes, computers or devices, to signify acknowledgment or receipt of message, as part of a communications protocol.
- Disable the writing on a log file

One must be attentive when doing so because any loss will not be registered and lost forever.

For large data-sets it is useful to use some additional structures called indexes, they are similar to the book indexes and act as a faster way to retrieve information, they might require more time during the insertion but makes the queries faster later, one primary index (basic one) is always defined for the id. How does it exactly work? Basically without an index Mongo will perform a simple table scan (like SQL) in which it has to look through all the “book” to find a query result, it is the same we would do if we didn’t have the index for our books we will have to read it whole until finding the point where we wanted to be. Indexing avoids this problem (more problematic if the database is large), it is an ordered list that points to its content. Since indexing slows down the modifications one must choose just a couple of indexes for any given collection, the tricky part is to decide which one. Fact : MongoDB gives a limit of 64 indexes!

The aggregation uses pipeline and options. The aggregation pipeline starts processing the documents of the collection and passes the result to the next pipeline in order to get result for example: \$match and \$group. We can use the same operator in different pipelines.

Mongo for many reasons (mainly commercial) offers also a SQL interface, we need the connector BI (Business Intelligence) it generates the relational schema and uses such schema to access the data.

3 GraphDB

What is a graph? It is a collection of nodes and edges which represents their relations. It has a lot of applications such as: social media, recommendations, Geo, Logistics network,

financial transaction graphs (for fraud detection), master data management, Bioinformatics, authorization and access control.

The labeled property graph model has the following characteristics:

- It contains nodes and relationships;
- Nodes contains properties (key : value pairs);
- Nodes can be labeled with one or many labels;
- Relationships are named and directed, with a start and end node;
- Relationships can contain properties like nodes.
- The relationship can be fine-grained or generic: for example in case of Address we can choose distinct relationship like HOME_ADDRESS or WORK_ADDRESS or DELIVERY_ADDRESS which is the fine-grained relationship or we could choose only address and specify in it which kind of address it is ADDRESS{type : 'home'} or the other ones, this method is called generic relationship. Usually it's preferred the generic one especially in cases where I need to find all the address of a client all I need to do is find the ADDRESS relationship, in the fine-grained I needed to find one by one all kind of addresses, just imagine if we had 100 types of addresses. On the other hand to find the DELIVERY_ADDRESS all I need to do is find ADDRESS{type:'delivery'}

A graph database (GD) can use either the native or non-native storage and processing engine.

Native Graph Storage is the one optimized for the native graph management & the non native graph storage stores the data in non graph based model but this model supports a graph query language : examples : Relational, Object oriented DB, Wide Column, in a relational for example in a join bomb we can use a graph to connect two tables. But the problem with the relational DBs and most of NoSQL DBs is that it lacks relationships. Moreover in SQL joining tables adds more complexity, and in case of sparse table with null-able column require special checking in the code, in the case of a market, just to see what a customer bought we need to do a lot of expensive joins or the customers that buy a specific product with other products for the recommendation systems. For the NoSQL DBs whether key-value, document or column-oriented, we might use the aggregation technique to see the relationship, but the relationship between aggregates aren't citizen in the data model and is costly operation since it's doesn't use index free adjacency, since they stay inside of aggregates with structure in form of nested maps and even after the aggregation there is no back link to point backward and run other interesting queries.

In a native graph storage the attributes and nodes and the referenced nodes are stored together, to optimize the graph processing engine. When we perform a query the graph model does not depend on the total number of nodes instead it remain nearly constant because it works locally to the portion of the graph which is connected to the base node, while the other SQL and NoSQL models will suffer in performance speed with the increase of data. Moreover we can add more data/nodes and relationship without disturbing the already existing model.

The processing engine uses index-free adjacency, meaning that connected nodes physically points to each other in the DB, this makes sure that the retrieval is faster but it comes at a cost, the efficiency of queries that do not use graph traversal, for example the writing time etc.

It's important to note that it's neither good nor bad to use native or non-native engine, simply one needs to choose one based on his/her needs, for example my DB is based on a non-graph backend (like MySQL) so it would be useful to use a non native graph storage.

The properties of the cypher language is :

1. Pattern-matching Query language
2. Humane language, easy to learn, read and understand
3. Expressive yet compact
4. Declarative : Say what you want, not how
5. Borrows from well known query languages especially SQL, yet clearly it's different enough to see that it deals with graphs and not SQL DBs.
6. Aggregation, Ordering, Limit
7. Update the Graph

A real example is the following: We want to manage a server farm, we define a relational model for managing it. We know that a user access to application which runs on a VM and each application uses a DB and a secondary DB. Each of the VM is hosted on a server which are placed in a rack structure which is managed by a load balancer.

The initial stage of modeling is similar in any kind of DB, we seek to understand and agree on the entities in the domain and how to interrelate, usually done on whiteboard with a diagram which is a graph. Next stage we seek a E-R (Entity-Relationship) diagram, which is another graph. After having a suitable logical model we map it into tables and relations. We keep are data in a relational DB, with it's rigid schema. But keeping the data normalized slows down the query time so we need to denormalize it, because the user's data model must suit the database engine not the user. Denormalizing we involve duplicate data to gain query performance, denormalizing is not a trivial task and we accept that there may be substantial data redundancy. The problems doesn't stop here, because once created if we need to modify it, which we will need to do in order to match the changes in the production environment, so we will need to do this work all again!

It's better in there cases to directly use the graph DBs, it will avoid the data redundancy and it can adapt really fast in case of a change in the DB.

Another graph traversal language is Gremlin, part of the Apache TinkerPop framework. In this domain specific language (DSL) expressions specify a concatenation of traversal steps, so you basically explain to gremlin step by step what to do.

4 Key-Value Model

It's the most simple and flexible model of the NoSQL family, where every key is assigned to a value, it is possible to assign a type to a value. The values are not query-able, such as a BLOB, where a BLOB(Binary Large Object) is a collection of binary data stored as a single entity in a DB, for example images, videos etc.:

An example is the amazon's cart system which uses DynamoDB a key-value system.

The basic operation in a key-valued models are:

- Insert a new key-value pair
- Delete a new key-value pair
- Update a new key-value pair
- Find a value given the key

There is no schema and the values of the data is opaque. The values can be accessed only through the key, and stored values can be anything : numbers, string, JSON, XML, images, binaries etc.

Thanks to the Hash based index, the key-value systems can scale out in a very efficient way. The Hash is a mathematical function that assign to a given key it's value, usually $h(x) = \text{value}$, usually it returns a pointer to where the data is stored not exactly the data itself, for example $h(x) = (x \text{ modulo } y)$ where y is the max length of hash table. There might a problem with the conflicts but they can be managed. Hashing also enables items in the DB to be retrieved quickly. The hash table can be easily distributed in a network, it is managed in pile so we can have a key(saved in the pile) x saved in a server and it's $\text{succ}(x)$ stored in a different server, thus scaling out really fast. The key value terminology is the following:

In a DHT(Distributed Hash Table) it is pretty simple to insert a key-value $(k1, v1)$ basically take the key as input and route messages to the node holding that key and store the value there, and to retrieve the value of $k1$ it simply finds the node with the key $k1$ and return it's value $v1$ from it.

5 Wide Column and BigTable

This models are an evolution, in a certain way, of the key-value models, when we start giving a structure to the value it becomes more complicated so we use wide column(Big Table) : The first model was introduced by Google(HBase) and later on by Facebook(Cassandra) some think that Cassandra is still a key-value model and not a wide column.

BigTable is a multidimensional map, which can be accessed by row key, column key and a timestamp. It is sorted, persistent and sparse.

We will consider the HBase BigTable Model :

The data is organized in tables, each table(the tables are multiversioned) is composed by the column-families that include columns, the cells within a column family are sorted physically and are usually very sparse with most of the cell having NULL value. BigTable is characterized by the row key, column key, timestamp, the row has the keys, column contains

the data and contents. The column is divided in families. The timestamp support the multiversion of modification to check how the data changed over time and still be able to access the latest one without any confusion. The data is without type since it is saved in bytes. The columns are dynamic. So to get a data given a key we need to transform our data in Bytes with a comand `.toByted("Key")` we can use python to modify the columns.

Best time to use Hbase is when one need to scale out, need random write and/or read, when we need to do thousand of operations per second on multiple TB of Data, when we need to know all the modification done on the data, when we need a well known and simple access. One can use a GraphDB with HBase see JanusGraph.

Cassandra: It started as a support for the fb inbox search, it was open sourced in 2008 by fb and then it became a top-level project. The data model is the same as HBase, the only difference is the way it is stored (storage model) and the program algorithms. We can say it is a restricted BigTable, we can have only one column family. It use a C* language very similar to SQL language.

If we divide our db in n db, called the fragmentation of data, the bottom-lake phenomena arises in which the slowest machine becomes the bottom-lake and the max time for a query is dependent on that machine. Another way is to replicate the data 2 on 2 such as if a machine is not accessible we can have that data from another machine. We can also combine the fragmentation and replication. The advantages of replication are:

- availability
- parallelism
- reduced data transfer.

while the disadvantages are:

- increased cost of updates
- increased complexity of concurrency control e.g. two people book a ticket at the same time solution : [...].

Data Transparency is very important so the users are not aware on the way we distribute the data.

Shared Everything : existed until 2000 (aprox) we have one big complex costly data base shares everything and can be very slow,

Share Disk : We have data saved on different disk connected btween them, no one uses it.

Share Nothing : every thing is separated it is very easy to scale out it Model used by noSQL models.

What to choose btwn Scaliblty or Avlblty? It depends on how much one wants to spend more availability means more money.

How to create replicas?

- take the data form master either the backup copy or the data itself (if we can stop the activity of the server) and move it.
- Using log file : to maintain the replica as same as as the source even during the transfer (near real time).

If you use Volume in project be attentive to the scalability!!!!

How MongoDB manages the distribution :

It uses Sharding : Every document has a key in mongodb so we define a shard key which defines the range of data. Ex. Key is surname so we can decide all the surname starting from A to K save in first partition and the other in the second.

The shard is basically a server so we need to use mongos (s=server) to make a query on a shard.

What is a Shard exactly?

It's a node of the cluster, it can be a single mongod or a replica set. MongoDB also automatically replicates the data and in one shard I will have a primary chunk where I store the data I wanted and secondary chunks where mongo replicated other data as backup just in case, the secondary is a read only data so I cannot do update queries on it.

How to configure a mongoserver?

Mongod -configsvr

We can have different mongos on same pc on different ports.

What happens to the query?

For the target query mongo selects the shard containing the data and then it's simplest

For the Scatter gather query we run query on all shard the collect the data and "join" it.

For the sorting we locally sort on all shards and then do a global sorting.

HBase each tool has a different terminology.

Hbase components is a subset of table's row (horizontal range partition), which is automatically done.

Hbase lives because of ZooKeeper.

Hbase is similar to mongodb and have the same flaw : If the master is broken the client cannot obtain any data and we have an error.

Cassandra on the other hand repairs this flaw since there is no master and all the nodes are considered the same peer to peer.

In cassandra since I can add or remove nodes with no downtime we have a transparent elasticity and scalability and since it's P2P architecture we obtain also the High Availability. Also cassandra uses ZooKeeper to find the replicas in other databases, given a node we decide the N number of following nodes in which the replica will be saved.

The data writing is separated in 3 stages : the first one is the log file writing which is essential, even if the data writing fails it doesn't matter because we have the log file. And the consistency is based on majority : if a certain number, which we decide, of the nodes agree that a certain data was written or read it is assumed to be true. Or use quorum which states the 50% + 1 nodes agree that something is written it is assumed true.

To delete the data it is easier to consider the data not available (like how recycle bin in OS), and follow it by compactation which reclaims the not available space.
